We Should At Least Be Able To Design Molecules That Dock Well

Tobiasz Cieplinski[1], Tomasz Danel[1], Sabina Podlewska[1],
Stanisław Jastrzębski[23]

Abstract

Designing compounds with desired properties is a key element of the drug discovery process. However, measuring progress in the field has been challenging due to the lack of realistic retrospective benchmarks, and the large cost of prospective validation. To close this gap, we propose a benchmark based on docking, a popular computational method for assessing molecule binding to a protein. Concretely, the goal is to generate drug-like molecules that are scored highly by SMINA, a popular docking software. We observe that popular graph-based generative models fail to generate molecules with a high docking score when trained using a realistically sized training set. This suggests a limitation of the current incarnation of models for de novo drug design. Finally, we propose a simplified version of the benchmark based on a simpler scoring function, and show that the tested models are able to partially solve it. We release the benchmark as an easy to use package available at https://github.com/cieplinski-tobiasz/sminadocking-benchmark. We hope that our benchmark will serve as a stepping stone towards the goal of automatically generating promising drug candidates.

1 Introduction

Designing compounds with some desired chemical properties is the central challenge in the drug discovery process [Sliwoski et al., 2014, Elton et al., 2019]. De novo drug design is one of the most successful computational approach that involves generating new potential ligands *from scratch*, which avoids enumerating explicitly the vast space of possible structures. Recently, deep learning has unlocked new progress in drug design. Promising results using deep generative models have been shown in generating soluble [Kusner et al., 2017a], bioactive [Segler et al., 2018], and drug-like [Jin et al., 2018b] molecules.

A key challenge in the field of drug design is the lack of realistic benchmarks [Elton et al., 2019]. Ideally, the generated molecule by a de novo method should be tested in the wet lab for the desired property. In practice, typically, a proxy is used. For example, the octanolwater partition coefficient or bioactivity is predicted using a computational model [Segler et al., 2018, Kusner et al., 2017a]. However, these models are often too simplistic [Elton et al., 2019]. This is aptly summarized in Coley et al. [2019] as "The current evaluations for generative models do not reflect the complexity of real discovery problems.". In contrast to

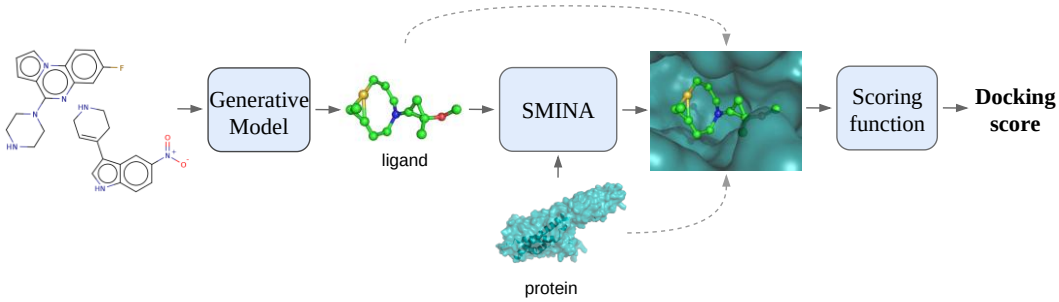

Figure 1: Visualization of the proposed docking-based benchmark for de-novo drug design methods. First, the proposed molecule (leftmost) is docked to the target's binding site using SMINA, a popular docking software. In the most difficult version of the benchmark, the final score is computed based on the ligand pose using the default SMINA docking score.

drug design, more realistic benchmarks have been used in the design of photovoltaics [PyzerKnapp et al., 2015] or in the design oof molecules with certain excitation energies [Sumita et al., 2018], where a physical calculation was carried out to both train models, and to evaluate generated compounds.

Our main contribution is a realistic benchmark for de novo drug design. We base our benchmark on docking, a popular computational method for predicting molecule binding to a protein. Concretely, the goal is to generate molecules that are scored highly by SMINA [Koes et al., 2013]. We picked Koes et al. [2013] due to its popularity and being available under a free license. While we focus on de novo drug design, our methodology can be extended to evaluate retrospectively other approaches to designing molecules. Code to reproduce results and evaluate new models is available online at https://github.com/cieplinski-tobiasz/sminadocking-benchmark.

Our second contribution is exposing limitation of currently popular de novo drug design methods for generating bioactive molecules. When trained using a few thousands compounds, a typical training set size, the tested methods fail to generate active structures according to the docking software. This suggest we should exercise caution when applying them in drug discovery pipelines, where we seldom have larger number of known ligands. We hope our benchmark will serve as a stepping stone to further improve these promising models.

The paper is organised as follows. We first discuss prior work and introduce our benchmark. Next, we use our benchmark to evaluate two popular models for de novo drug design. Finally, we analyse why the tested models fail on the most difficult version of the benchmark.

2 Docking-based benchmark

We begin by briefly discussing prior work and motivation. Next, we introduce our benchmark.

2.1 Why do we need yet another benchmark?

Standardized benchmarks are critical to measure progress in any field. Development of large-scale benchmarks such as the ImageNet was critical for the recent developments in artificial intelligence

[Deng et al., 2009, Wang et al., 2018]. Many new methods for de novo drug design are conceived every year, which motivates the need for a systematic and efficient way to compare them [Schneider and Clark, 2019].

De novo drug design methods are typically evaluated using *proxy tasks* that circumvent the need to test the generated compounds experimentally [Jin et al., 2018a, You et al., 2018, Maziarka et al., 2020, Kusner et al., 2017b, Gómez-Bombarelli et al., 2016]. Optimizing the octanol-water partition coefficient (logP) is a common example. The logP coefficient is commonly computed using an atom-based method that involves summing contribution of individual atoms [Wildman and Crippen, 1999, Jin et al., 2018a], which is available in the RDKit package [Landrum, 2016]. Due to the fact that it is easy to optimize the atom-based method by producing unrealistic molecules [Brown et al., 2019], a version that heuristically penalizes hard to synthesize compounds is used in practice [Jin et al., 2018a]. This example illustrates the need to develop more realistic ways to benchmark these methods. Another example is QED score [Bickerton et al., 2012] which is designed to capture *druglikeliness* of a compound. Finally, some approacches use a model (e.g. a neural network) to predict bioactivity of the generated compounds Segler et al. [2018]. Similarly to logP, these two tasks are also possible to optimize while producing unrealistic molecules. This is aptly summarized in Coley et al. [2019] as

> "The current evaluations for generative models do not reflect the complexity of real discovery problems."

Interestingly, besides the aforementioned proxy tasks, more realistic proxy tasks are rarely used in the context of evaluating de novo drug design methods. This is in contrast to evaluation of generative models for generating photovoltaics [Pyzer-Knapp et al., 2015] or molecules with certain excitation energies [Sumita et al., 2018]. One notable exception is Aumentado-Armstrong [2018] who try to generate compounds that are active according to the DrugScore [Neudert and Klebe, 2011], and then evaluate the generated compounds using rDock [Ruiz-Carmona et al., 2014]. This lack of the overall diversity and realism in the typically used evaluation methods motivates us to propose our benchmark.

2.2 Docking-based benchmark

Our docking-based benchmark is defined by: (1) docking software that computes for a generated compound its pose in the binding site, (2) a function that scores the pose, (3) a training set of compounds with an already computed docking score.

The goal is to generate a given number of molecules that achieve the maximum possible docking score. For the sake of simplicity, we do not impose limits on the distance of the proposed compounds to training set. Thus a simple baseline is to return the training set. Finding similar compounds that have a higher docking score is already prohibitively challenging for current state-of-the-art methods. As the field progresses, our benchmark can be easily extended to account for the similarity between the generated compounds and the training set.

Finally, we would like to stress that the benchmark is not limited to de novo methods. The benchmark is applicable to any other approaches such as virtual screening. The only limitation required for a fair comparison is that docking is performed only on the supplied training set.

2.3 Instantiation

As a concrete instantiation of our docking-based benchmark, we use SMINA [Koes et al., 2013] due to its wide-spread use and being offered under a free license. To create the training set, we download from the ChEMBL [Gaulton et al., 2016] database molecules tested against popular drug-targets: 5-HT1B, 5-HT2B, ACM2, and CYP2D6. For 5-HT1B the final dataset consists in 1991 molecules, out of which 1148 are active (Ki < 100nm) and 743 are inactive molecules (Ki > 1000nm). We list sizes of the datasets in Table 2.

We dock each molecule using default settings in SMINA to a manually selected binding site coordinate. Protein structures were downloaded from the Protein Database Bank, cleaned and prepared for docking using Schrodinger modeling package. The resulting protein structures are provided in our code repository. We describe further details on the preparation of the datasets in Appendix C.

Starting from the above, we define the following three variants of the benchmark. In the first variant, the goal is to propose molecules that achieve the smallest SMINA docking score used in score only mode, defined as follows:

$$\begin{aligned}\text{Docking score} = &-0.035579 \cdot \text{gauss}(o=0, w=0.5)\\ &-0.005156 \cdot \text{gauss}(o=3, w=2)\\ &+0.840245 \cdot \text{repulsion}\\ &-0.035069 \cdot \text{hydrophobic}\\ &-0.587439 \cdot \text{non\_dir\_h\_bond}\end{aligned},$$

where all terms are computed based on the final docking pose. The first three terms measure the steric interaction between ligand and the protein. The fourth and the fifth term look for hydrophobic and hydrogen bonds between the ligand and the protein. We include in Appendix A a detailed description of all the terms.

Next, we propose two simpler variants of the benchmark based on individual terms in the SMINA scoring function. In the *Repulsion* task, the goal is to only minimize the repulsion component, which is defined as:

$$(a_1, a_2) = \begin{cases} d_{\text{diff}}(a_1,a_2)^2, & d_{\text{diff}}(a_1,a_2) < 0 \\ 0 & \text{otherwise} \end{cases},$$

repulsion

where $d_{\text{diff}}(a_1,a_2)$ is the distance between the atoms minus the sum of their van der Waals radii. Distance unit is Angstrom (10^{-10}m).

The third task, *Hydrogen Bond Task*, is to maximize the non_dir_h_bond term:

$$\begin{cases} 0, & (a_1,a_2) \text{do not form hydrogen bond} \\ \end{cases}$$

$$\text{non\_dir\_h\_bond}(a_1, a_2) = \begin{cases} 1, & d_{\text{diff}}(a_1, a_2) < -0.7 \\ 0, & d_{\text{diff}}(a_1, a_2) \geq 0 \\ \frac{d_{\text{diff}}(a_1, a_2)}{-0.7} & \text{otherwise.} \end{cases}$$

To make the results more stable, we average the score over the top 5 best-scoring binding poses. Finally, to make the benchmark more realistic, we filter the generated compounds using the Lipinski rule, and discard molecules with molecular weight lower than 100.

3 Results and discussion

In this section, we evaluate two popular models for de novo drug design on our benchmark.

3.1 Models

We compare two popular models for de novo drug design. Chemical Variational Autoencoder (CVAE) [Gómez-Bombarelli et al., 2018] applies Variational Autoencoder [Kingma and Welling, 2013] by representing molecules as strings of characters (using SMILES encoding). This approach was later extended by Grammar Variational Autoencoder (GVAE) [Kusner et al., 2017a], which ensures that generated compounds are grammatically correct.

3.2 Experimental details

To generate active compounds, we follow a similar approach to in Gómez-Bombarelli et al. [2018] and Kusner et al. [2017a]. First, we fine-tune a given generative model for 5 epochs on the training set ligands, starting from weights made available by the authors[1]. All hyperparameters are set to default values used in Gómez-Bombarelli et al. [2018] and Kusner et al. [2017a]. Additionally, we use the provided scores to train a multilayer perceptron (MLP) to predict the target (e.g. the SMINA scoring function) based on the latent space representation of the molecule.

To generate compounds, we first take a random sample of the model latent space by sampling from a Gaussian distribution with the standard deviation of 1 and the mean of 0. Starting from this point in the latent space, we take Z gradient steps to optimize the output of the MLP. Based on this approach we generate 250 compounds from the model.

All other experimental details, including hyperparameter values used in the experiments, can be found in Appendix B.

In the experiments, we compare to three baselines: (1) random compounds from ZiNC, (2) random unseen in training active compounds (Ki < 100nm), (3) random unseen in training inactive compounds (Ki > 1000nm).

3.3 Results

In this section, we use the above procedure to generate compounds for the three targets defined in Section 2.3. Table 1a summarizes the results on all three tasks. Below we make several observations.

[1] Available at https://github.com/aspuru-guzik-group/chemical_vae/tree/master/models/zinc and at https://github.com/mkusner/grammarVAE/tree/master/pretrained.

First, we observe that CVAE and GVAE models fail to generate compounds that achieve higher scores than the three baselines. In particular, both models produce compounds that achieve on average docking scores below the mean in the training set (-8.267). Even looking at the Top 1%, the achieved scores are below the mean. This is reminiscent of results in Gao and Coley [2020]. They show that de novo models tend to generate difficult to synthesize molecules, even if optimizing for a proxy of synthesability. Similarly, even though we optimize for docking score using the MLP, the models fail to optimize the actual score. We will analys this phenomenon more closely in Section 3.4.

The next two tasks are easier to solve. On the Repulsion task, both models improve upon the baselines. GVAE generates compounds with remarkably low repulsion that is an

	5HT1B	5HT2B	ACM2	CYP2D6

(b) Repulsion task

	5HT1B	5HT2B	ACM2	CYP2D6
ZiNC	1.547 (4.983)	0.971 (3.379)	1.012 (5.805)	0.634 (4.533)
Inactives	1.258 (3.358)	0.945 (3.216)	0.948 (5.455)	0.689 (4.363)
Actives	1.698 (4.994)	1.095 (3.037)	1.124 (4.025)	0.475 (1.551)
CVAE	1.234 (5.059)	0.818 (3.585)	0.717 (4.241)	0.583 (4.620)
GVAE	2.581 (11.225)	2.111 (6.525)	2.771 (10.071)	2.339 (7.548)

(c) Hydrogen Bonding task

Table 1: Benchmark results. In Score Function, the goal is to propose 250 compounds achieving the lowest mean SMINA docking score towards a given target. Each cell reports the mean score for all compounds, and for the top 1% of compounds in the parenthesis. We observe that for Score Function task CVAE and GVAE fail to outperform ZiNC (a random sample of 250 compounds from the ZiNC database). Missing results ("-") indicate that the model failed to generate 250 molecules that satisfy the drug-like filters (described in the text).

order of magnitude lower (0.039) than the best score observed in the training set (0.322). This however should be interpreted with caution. It is possible to minimize repulsion by avoiding docking to the binding site, which might explain why Inactives tend to have lower repulsion than Actives. As such we suggest to treat the Repulsion task as a form of a unit test for the validity of the generating procedure.

The Hydrogen Bond task difficulty lies between the first two tasks. The mean score of molecules generated by GVAE is 1.52 times larger than the mean score of Actives (2.24 times larger for Top 1%). Contrarily, CVAE Top 1% results are worse the ones in Inactives dataset. This suggests that maximizing the non_dir_h_bond term in Equation A is harder than minimizing the repulsion term, but is still an easier task than optimizing the whole docking score.

Stronger results on the Repulsion and Hydrogen Bond tasks show it is feasible to optimize individual components of the score. This suggests that solving SMINA Score task is an attainable goal.

Finally, our results also suggest that generative models applied to de novo drug discovery pipelines might require substantial more data to generate active compounds than is typically available for training. In particular on the 5-HT1B receptor, despite using a realistically sized training set of over one thousand compounds, the achieved docking scores are worse than in a random sample from the ZiNC dataset. Docking score is only a simple proxy of the actual binding affinity, and as such it should worry us that it is already challenging to optimize.

	5HT1B	5HT2B	ACM2	CYP2D6
Dataset size	1891	1194	2341	4200

Table 2: Sizes of the dataset used in the benchmark. The corresponding test dataset comprises of 20% of the whole dataset, and the rest of it is used in training.

3.4 Analysis

In this section, we investigate why do CVAE and GVAE models fail to generate compounds that achieve high docking scores.

The most natural hypothesis is that predicting docking score is difficult. Our procedure uses the gradient of the MLP to generate active compounds. If the model fails at predicting activity, it is reasonable to assume it also fails to guide the generating process towards active compounds.

	5HT1B	5HT2B	ACM2	CYP2D6
CVAE	-60.071 (-58.792)	-28.958 (-30.205)	-354.084 (-352.818)	-515.886 (-377.572)
GVAE	-36.565 (-25.608)	-50.412 (-47.629)	-66.009 (-53.335)	-55.021 (-47.307)

Table 3: Predicted docking score towards 5HT1B by the MLP for the compounds presented in Table 1a. Comparing to Table 1a, we can observe that the predicted docking scores are two, three or even four orders of magnitude overestimating the true activity.

Recall that both models failed to generate compounds that achieve better docking scores towards 5HT1B than in particular a random sample from the ZiNC dataset (see Table 1a). However, the MLP predicts that these compounds are active towards 5HT1B. We show this in Table 3. This

discrepancy between MLP predictions and actual docking scores strongly suggest that modeling the docking score is the bottleneck.

To better quantify this effect, we measure the root mean squared error (MSE) between the predicted and the true docking score on two datasets: (1) 100 random samples of latent space from Gaussian distribution (*Gauss*), and (2) 250 molecules generated using gradient latent space optimization (*Generated*). We compare this to SMINA by redocking compounds and measuring the discrepancy between the two docking runs (*SMINA*).

Table 4 reports the results, and Figure 2 shows the predicted docking score against the true docking score on the compounds generated by CVAE. We observe that on all subsets the RMSE is three to four orders of magnitude higher than RMSE between two docking runs (SMINA). This shows that using better models for predicting docking scores is a promising avenue for improving results on the benchmark.

	MLP	SMINA
Gauss	4.064	0.004
Generated	56.062	0.009

(a) CVAE

	MLP	SMINA
Gauss	8.24	0.004
Generated	33.646	0.018

(b) GVAE

Table 4: Root mean square error between the predicted and the true docking scores for CVAE (left) and GVAE (right), compared to the difference between two runs of the docking software (SMINA).

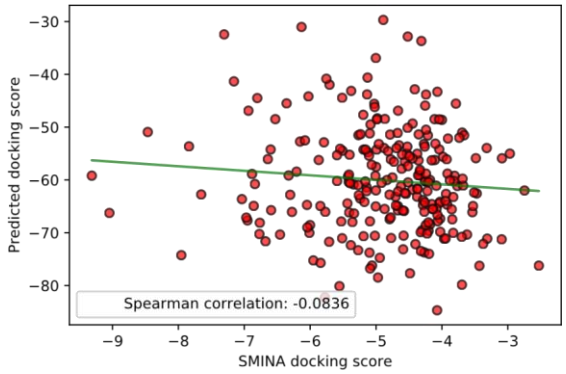

Figure 2: The predicted docking score (y axis) versus the true docking score (x axis) for the 250 compounds generated by CVAE. Improving modeling of the docking score is a promising avenue for improving on the benchmark.

4 Conclusion

As concluded by Coley et al. [2019], "the current evaluations for generative models do not reflect the complexity of real discovery problems". In this work, we proposed a new, more realistic, benchmark tailored to de novo drug design using docking score as the target to optimize. Code to

evaluate new models is available at https://github.com/cieplinskitobiasz/smina-docking-benchmark.

Our results also suggest that generative models applied to de novo drug discovery pipelines might require substantial more data to generate realistic compounds than is typically available for training. Despite using over 2000 compounds for training (for the CYP2D6 target), the achieved docking scores are worse than in a random sample from the ZiNC dataset. Docking score is only a simple proxy of the actual binding affinity, and as such it should worry us that it is already challenging to optimize.

On a more optimistic note, the tested models were able to optimize the number of hydrogen bonds to the binding site, which is a term in the SMINA scoring function. This suggests that producing compounds that optimize docking score based on the provided dataset is an attainable, albeit challenging, task. We hope our benchmark better reflects "the complexity of real discovery problems" and will serve as a stepping stone towards developing better de novo models for drug discovery.

A Default SMINA scoring function

We include the definitions of SMINA's default scoring function components and weights used for calculating docking score in score only mode. a_1 and a_2 denote atoms, $d(a_1,a_2)$ is the distance between atoms, d_{opt} is the sum of their van der Waals radii and $d_{\text{diff}}(a_1,a_2) = d(a_1,a_2) - d_{\text{opt}}(a_1,a_2)$. Distance unit is Angstrom (10^{-10}m).

$$\begin{aligned}\text{Docking score} = &-0.035579 \cdot \text{gauss}(o=0, w=0.5)\\ &-0.005156 \cdot \text{gauss}(o=3, w=2)\\ &+0.840245 \cdot \text{repulsion}\\ &-0.035069 \cdot \text{hydrophobic} -\\ &0.587439 \cdot \text{non\_dir\_h\_bond}\end{aligned}$$

$$\text{gauss}(a_1,a_2) = \exp\left(-\left(\frac{d_{\text{diff}}(a_1,a_2)-o}{w}\right)^2\right) \qquad !$$

$$\text{repulsion}(a_1,a_2) = \begin{cases} (d_{\text{diff}}(a_1,a_2))^2, & d_{\text{diff}}(a_1,a_2) < 0 \\ \end{cases}$$

$$0, \quad \text{otherwise}$$

$$\begin{cases} 0, & not\_hydrophobic(a_1) \text{ or } not\_hydrophobic(a_2) \\ 1, & d_{\text{diff}}(a_1,a_2) < 0.5 \end{cases}$$

$$\text{hydrophobic}(a_1,a_2) = \begin{cases} 0, & d_{\text{diff}}(a_1,a_2) \geq 1.5 \\ 1.5 - d_{\text{diff}}(a_1,a_2), & \text{otherwise} \end{cases}$$

$$\begin{cases} 0, & (a_1, a_2) \text{ do not form hydrogen bond} \\ 1, & d_{\text{diff}}(a_1,a_2) < -0.7 \end{cases}$$

$$\text{non\_dir\_h\_bond}(a_1,a_2) = \begin{cases} 0, & d_{\text{diff}}(a_1,a_2) \geq 0 \\ \frac{d_{\text{diff}}(a_1,a_2)}{-0.7}, & \text{otherwise} \end{cases}$$

B Model details

We include hyperparameters and training settings used in our models. Our code is available at https://github.com/cieplinski-tobiasz/smina-docking-benchmark.

MLP is used to predict docking score from CVAE or GVAE latent space representation of molecule. It is a simple feed forward neural network with one hidden layer. Hyperparameters of this model are listed in 5.

	Parameter
Training epochs	50
Layers number	1
Hidden layer dim	1000
Loss function	Mean Squared Error
Optimizer	Adam
Learning rate	0.001

Table 5: MLP hyperparameters

Both Chemical VAE and Grammar VAE are based on variational autoencoder model with stacked convolution layers in its encoder part and stacked GRU layers in decoder part. What differs them is the way that SMILES is encoded to one hot vector. Chemical VAE encodes each character of SMILES to separate one-hot vector, while Grammar VAE forms a parse tree from SMILES and encodes the parse rules. Details for CVAE are listed in 6 and for GVAE in 7.

	Parameter
MLP learning rate	0.05

MLP descent iterations	50
Fine-tuning batch size	256
Fine-tuning epochs	5
Latent space dim	196
Encoder convolution layers number	4
Decoder GRU layers number	4

Table 6: Chemical VAE hyperparameters

	Parameter
MLP learning rate	0.01
MLP descent iterations	50
Fine-tuning batch size	256
Fine-tuning epochs	5
Latent space dim	56
Encoder convolution layers number	3
Decoder GRU layers number	3

Table 7: Grammar VAE hyperparameters

C Dataset details

The compound sets were downloaded from the ChEMBL database. All records referring to human- and rat-based records were taken into account. Compunds with Ki values below 100 nM (later referred to as active compounds) and above 1000 nM (inactive ones) were taken into account. Only binding data were considered, it was assumed that IC50 = Ki/2. The compound protonation states were generated for pH = 7.4.

The crystal structures for docking were fetched from the PDB database, the following structures were used in the study: 4IAQ for 5-HT1B, 4NC3 for 4-HT2B, 3UON for ACM2, and 3QM4 for CYP3D6. The Protein Preparation Wizard from the Schrodinger molecular modeling package was used for protein preparation for docking.
